IL-10 Measurement in Aqueous Humor for Screening Patients with Suspicions of Primary Intraocular Lymphoma

Nathalie Cassoux,1 Alain Giron,2 Babram Bodaghi,1 Thi H. C. Tran,1 Sylvie Baudet,5 Frédéric Davy,3 Chi C. Chan,4 Phuc Leboang,1 and Hélène Merle-Béral5

PURPOSE. To determine the value of IL-10 measurement in aqueous humor (AH) for screening in primary intraocular lymphoma (PIOL).

METHODS. One hundred consecutive diagnostic or therapeutic vitrectomies were performed in patients with uveitis. During surgery, 100 µL of both AH and pure vitreous was taken. IL-10 levels were determined with a standard quantitative sandwich enzyme immunoassay technique. Patients were distributed in two groups: 51 patients with proven PIOL, 108 patients with uveitis divided into 74 with uveitis of proven etiology and 34 with idiopathic uveitis. Groups were compared by ANOVA and the Tukey-Kramer test or nonparametric Wilcoxon test. Distributions were compared by using the χ2 test. Segmentation was derived from the ROC curves by choosing a tradeoff between sensitivity and specificity.

RESULTS. In patients with PIOL, IL-10 mean values were 2205.5 pg/mL (median: 1467 pg/mL) in the vitreous and 543.4 pg/mL (median: 424 pg/mL) in AH. In patients with uveitis (idiopathic and diagnostic uveitis), mean values were 26.6 pg/mL (median: 8 pg/mL) in the vitreous, and 21.9 pg/mL (median: 8 pg/mL) in AH. IL-10 mean values were significantly different between patients with PIOL and patients with uveitis (P < 10-5). The areas under the curves were 0.989 and 0.962 for vitreous and AH, respectively. A cutoff of 50 pg/mL in the AH was associated with a sensitivity of 0.89 and a specificity of 0.93. In the vitreous, a cutoff value of 400 pg/mL yielded a specificity of 0.99 and a sensitivity of 0.8.

CONCLUSIONS. Diagnosis of PIOL is often made months or years after the initial onset of ocular symptoms. Cytology remains the gold standard for diagnosis. However, measurement of IL-10 in the AH is a good screening test to reduce diagnostic delays. (Invest Ophthalmol Vis Sci. 2007;48:3253–3259) DOI: 10.1167/iovs.06-04051

Primary intraocular lymphoma (PIOL) is a subset of primary central nervous system lymphoma (PCNSL). It is an aggressive, diffuse, large B-cell lymphoma and is generally restricted to the eye and central nervous system (CNS) compartments.1-3 Ocular involvement occurs in 20% to 25% of patients with PCNSL. Of those patients initially affected by PIOL, 56% to 85% later develop a cerebral tumor.4,5 PCNSL presents 4% to 6% of all primary cerebral tumors and 1% to 2% of extranodal lymphomas. Within the past two decades, the incidence of PCNSL has approximately tripled in the United States.6

Patients with PIOL typically report blurred vision and floaters. These symptoms are frequently attributed to chroniciritis or uveitis over the course of several months or even years. The gold standard for diagnosis is cytologic examination of the vitreous after a diagnostic vitrectomy. However, cytologic diagnosis is difficult because of the fragility of lymphoma cells.7 False-negative cytology results have been reported in approximately 30% of vitreous biopsy specimens collected from a referral center.8

New tools (i.e., cytokine assessment and various other molecular techniques) have recently been developed to improve the diagnostic yield.5 B lymphoma cells are characterized by the production of several cytokines—in particular, IL-10.9 An increase of IL-10 levels in the vitreous or an increase in the IL-10/IL-6 ratio to greater than 1 has been reported in the vitreous of patients with PIOL.5,10-12 In contrast, an early study on the subject, Akpek et al.13 reported that this ratio may not always be associated with PIOL.

PCNS lymphoma remains a disease of poor prognosis, especially if the eye is involved. Recent data suggest that early diagnosis and treatment result in better disease control and in a longer survival period.14 In most series, diagnosis is made after a mean period of 12 to 24 months.8,15,14 To reduce this period for diagnosis, we studied the value of IL-10 measurements after an anterior chamber tap, or paracentesis (ACP), as a potential screening test. The samples were collected prospectively. IL-10 measurements were performed in sample lots of 20 every 15 days, and data were then examined once they were all pooled. Clinical data were extracted retrospectively from patients' files at the end of enrollment.

An increase of IL-10 levels may indicate to clinicians that an earlier diagnostic vitrectomy may be needed to confirm a diagnosis of PIOL. If PIOL is diagnosed earlier, CNS involvement, a poor prognostic sign, may be prevented.14

MATERIALS AND METHODS

Patients

Between 1997 and 2002, 3350 patients were referred to the Department of Ophthalmology, Pitié-Salpêtrière Hospital, Paris, France, for uveitis. A diagnosis was established in roughly 60% of the cases. If the origin of the uveitis remained uncertain after the clinical history was reviewed and an ophthalmic examination was performed, a complete laboratory workup and additional specialized medical consultations were performed. When the etiology remained unknown or if a malignancy or an infectious condition was suspected, an ACP was proposed

for IL-10 measurement or polymerase chain reaction (PCR) for viral, Toxoplasma gondii, or bacterial DNA amplification. A diagnostic vitrectomy was recommended when the aqueous samples were noncontributory.

If a complication was associated (i.e., retinal detachment, epiretinal membrane, or neovascularization) related to infectious or noninfectious uveitis, vitreoretinal surgery was performed. On the occasion of this surgical procedure, aqueous humor (AH) and vitreous were systematically collected for IL-10 measurements.

One hundred sixty-seven consecutive vitrectomies were performed, during the same period, in patients with uveitis, either related or unrelated to a neoplasm, for diagnostic or therapeutic purposes. Vitreous samples were systematically collected prospectively for cytologic analysis and IL-10 measurement. AH was also collected after an ACP before vitrectomy or during a surgical procedure. In addition, according to clinical suspicion of PIOL, molecular techniques were applied to the vitreous specimens to screen for clonal IgH rearrangements. PCR was also applied for the diagnosis of ocular toxoplasmosis, viral retinitis, and bacterial infections.

In some patients, the ACP was performed before diagnostic vitrectomy, and a second paracentesis was performed during the diagnostic vitrectomy according to our protocol. In cases of therapeutic vitrectomy, paracentesis was performed during the surgical procedure.

Originally, 167 patients were enrolled in the study. The patients were distributed in two groups. The first comprised 51 patients with PIOL diagnosed by cytologic analysis of the vitreous (47 patients) or by histopathologic analysis of brain or retinal biopsy specimens (three cerebral, one retinal). The second group consisted of 116 patients with diagnosed uveitis and an associated condition (n = 74; i.e., sarcoidosis, Behçet disease, HLA B27-related uveitis, ocular toxoplasmosis, or viral retinitis) or with idiopathic uveitis (n = 42).

All patients (PIOL, uveitis with diagnosis, idiopathic uveitis) were observed for a mean of 2 years, except 8 patients with idiopathic uveitis lost to follow-up who were excluded from the study, leaving 34 participants with idiopathic disease. All etiologies and associated conditions that composed the nonidiopathic group of patients and type of vitreoretinal surgery (diagnostic or therapeutic vitrectomy) are summarized in Table 2. Patients who underwent vitreoretinal surgery for uveitis-related retinal detachment were referred to emergency at an acute phase of the disease. No corticosteroids were given before surgery, to limit the influence of the treatment on secretion of proinflammatory cytokines.

All patients gave their informed consent after the nature of the study had been fully explained to them. All data were treated confidentially. The study was performed with the approval of the hospital review board. This research conformed to the scientific principles embodied in the World Medical Association Declaration of Helsinki as revised in 1989.

Methods
During or before surgery, 100 µL of AH was taken from all the patients after an ACP, for IL-10 measurement and microbiologic analysis, depending on clinical suspicion. If the ACP was performed before vitrectomy it was done under topical anesthesia with a 30-gauge needle in the operating theater with a surgical microscope. If it was performed during the surgery or vitrectomy, the patient was under general anesthesia. All etiologies and associated conditions that composed the nonidiopathic group of patients and type of vitreoretinal surgery (diagnostic or therapeutic vitrectomy) are summarized in Table 2. Patients who underwent vitreoretinal surgery for uveitis-related retinal detachment were referred to emergency at an acute phase of the disease. No corticosteroids were given before surgery, to limit the influence of the treatment on secretion of proinflammatory cytokines.

All patients gave their informed consent after the nature of the study had been fully explained to them. All data were treated confidentially. The study was performed with the approval of the hospital review board. This research conformed to the scientific principles embodied in the World Medical Association Declaration of Helsinki as revised in 1989.

Results
Demographic Data
Mean age was 55.5 years in subjects with uveitis, but 25% were older than 70 years. The mean age of patients with PIOL was 69.4 years (median, 72), and 25% of patients were younger than 70 years. There were no significant differences for age and sex between subjects with nonidiopathic uveitis and those with idiopathic uveitis. Patients with PIOL were older (P < 10⁻⁵) than subjects with uveitis and were more predominantly female (P = 0.02; Table 1).

Differences in age distribution were observed among the uveitis group depending on the diagnosis (P = 0.04). Patients with bacterial infections were typically older. More women were affected by parasitic (toxoplasmosis or toxocariasis) infections and more men were affected by viral infections.

Various etiologies or associated conditions were found in the group of patients with nonidiopathic uveitis. Most were affected by infectious uveitis (48 patients). The others were affected by noninfectious uveitis restricted to the eyes (i.e., birdshot, Fuchs' heterochromic cyclitis) or associated with...
systemic disease (i.e., sarcoidosis, Behçet disease, or HLA B27-related uveitis). Most of the patients in this group underwent vitreoretinal surgery to cure retinal detachment, to treat proliferative retinopathy due to occlusive vasculitis, or to remove vitreous opacities or an epiretinal membrane (Table 2).

Vitrectomy contributed to the diagnosis of PIOL in 47 cases. In four patients, cytology was negative. In one, diagnosis was made after a retinal biopsy. In three patients, diagnosis was made after a stereotaxic brain biopsy. For these four cases, slides were sent for microdissection that was positive in two patients (one Bcl2 translocation, one Ig heavy chain rearrangement).

**Results of IL-10 Measurement in AH and in the Vitreous**

IL-10 was measured in the vitreous of 49 of 51 patients with PIOL, 69 of 74 patients with nonidiopathic uveitis, and all 34 patients with idiopathic uveitis. IL-10 was measured in the AH of 45 of 51 patients with PIOL, 57 of 74 patients with uveitis, and 31 of 34 patients with idiopathic uveitis.

In some patients, samples were taken only from the AH or the vitreous. For example, 17 patients who agreed only to diagnostic vitrectomy, refused concomitant ACP. In two patients affected by lymphoma both in the eye and in the CNS, we performed only an ACP, because diagnosis had been made by brain biopsy.

In patients with PIOL, mean/median levels of IL-10 were 2205.5/1467 pg/mL in the vitreous and 543.4/424 pg/mL in the AH, but we observed a subgroup (14/51 patients) in whom levels were between 3500 and 8000 pg/mL in the vitreous and 700 and 2000 pg/mL in the AH (Table 3).

In subjects with uveitis (idiopathic or nonidiopathic), mean/median levels of IL-10 were 26.6/8 pg/mL in the vitreous and 21.9/8 pg/mL in the AH.

Detailed analysis of subjects with uveitis showed that the highest levels of IL-10 in the AH were mainly in cases of viral or parasitic uveitis (acute retinal necrosis or ocular toxoplasmosis with severe vitritis). A nonparametric Kruskal-Wallis ANOVA used to compare the different diagnoses of control patients with uveitis indicated a significant global difference ($P < 0.02$) in the AH and a nearly significant test in the vitreous ($P = 0.06$). The difference was mainly caused by the higher concentrations in the infectious uveitis groups (viral, bacterial, or parasitic groups), whereas levels in idiopathic uveitis were in the low range.

Mean IL-10 levels were significantly greater in the 51 patients with PIOL than in the 108 patients with uveitis (nonid-

Data are expressed in picograms per milliliter.

The table shows the distribution of IL-10 in vitreous and aqueous humor across different diagnostic categories. For example, in PIOL patients, the mean IL-10 level is 2205.5 pg/mL, while in idiopathic uveitis, the median IL-10 level is 8 pg/mL.

**Discussion**

In this study, we have shown that IL-10 measurement in AH obtained from an anterior chamber aspiration may be a valuable tool for the diagnosis of PIOL. ACP is a safe procedure that is currently used for diagnosis of infectious diseases in the eye. After an extensive literature survey (National Library of Medicine; search terms: anterior chamber paracentesis, side-effect, corneal abscess, and endophthalmitis), we were able to find only a few case reports of complications after ACP. One patient presented with a corneal abscess, and one patient presented with bacterial endophthalmitis.21,22 Van der Lelij and Rothova23 evaluated the safety of the ACP in 361 patients. None of the patients experienced complications. However, one patient had a traumatic cataract that developed after ACP performed with the slit lamp while the patient was in an upright position. More recently, a study conducted by Cheung et al.24 of 70 patients with uveitis who underwent ACP with a slit lamp for diagnostic purposes did not report any complications due to the procedure. In our study, we also did not observe any complications due to ACP.

In this study, elevated IL-10 levels in the AH were strongly associated with PIOL. Elevated IL-10 in the vitreous was first described by Chan et al.10 in PIOL in 1995 and was found to be associated with the number of malignant cells. An increase of IL-6 levels in the vitreous, in contrast, was found to be associated with nonmalignant intraocular inflammation.25 Whitcup et al.11 later showed that an IL-10/IL-6 ratio greater than 1 is associated with intracellular lymphoma. The ratio calculation was criticized, because they used diluted vitreous samples to measure cytokine levels.

In our study we measured IL-10 levels only in undiluted ocular fluids. We decided not to calculate IL-10/IL-6 ratios in view of designing a less expensive and simpler test on both the AH and vitreous. High IL-10 levels were found in ocular fluids. We decided not to calculate IL-10/IL-6 ratios in view of designing a less expensive and simpler test on both the AH and vitreous.
PIOL had levels of IL-10 over the threshold of 50 pg/mL. We also found that, in most of the patients, elevated levels of IL-10 were present in both the AH and vitreous.

Typically, there are no or very few cells in the anterior chamber of patients with PIOL. The presence of IL-10 in the AH is probably due to diffusion from the posterior to the anterior chamber. Such diffusion is may vary from one patient to another, thus explaining why the correlation coefficient is not very strong between levels in the two compartments. We cannot explain why in some rare patients, we found very low levels of IL-10 in the AH while high levels of this cytokine were measured in the vitreous. The latter two patients were phakic with a quiet anterior chamber and a dense vitritis. At this point, we cannot exclude a technical problem during ELISA processing.

Based on the ROC curve (Fig. 4), including IL-10 levels measured in AH of patients with PIOL versus IL-10 levels in both nonidiopathic and idiopathic cases of uveitis we established a threshold in AH for further screening patients. Our statistical analysis showed that for an IL-10 level of 50 pg/mL, sensitivity was 89% and specificity 93%. We considered this level to be the best compromise between sensitivity and specificity.

In six cases (false negative) of proven PIOL, we found IL-10 levels in AH below the measuring threshold of 50 pg/mL. In each case, ocular involvement was limited to minimal vitritis associated with some rare retinal infiltrates. The Department of Neurology referred all patients who were admitted for cerebral lymphoma. For one patient, diagnosis was made immediately after diagnostic vitrectomy. In the other five cases, diagnostic vitrectomy was noncontributory.

Examples of PIOL associated with low levels of IL-10 have been described by Akpek et al.13 and Buggage et al.26 However, these cases were difficult to analyze, because diluted vitreous samples from the vitrector cassette had been used to assay the cytokines. Akpek et al.13 also mentioned cases of uveitis associated with increased IL-10 levels in the vitreous.

We also observed five false-positive cases that had IL-10 levels above the threshold in vitreous or AH. All these patients presented with infectious uveitis. Three patients had an acute retinal necrosis syndrome due to herpes simplex virus in two cases and varicella zoster virus in one case. In all these cases, diagnosis was made clinically according to diagnostic criteria established by the American Uveitis Society and after detection of viral genomes using PCR techniques. The remaining two cases were due to toxoplasmosis (PCR-positive vitreous). In all

**FIGURE 2.** Mean ± SD of IL-10 level in the AH by diagnostic group.

**FIGURE 3.** Correlation between IL-10 levels in AH and vitreous (Z, PIOL patients; X, idiopathic uveitis; ■, uveitis).
five cases, vitrectomy was necessary to treat retinal detachment associated with a severe inflammatory reaction in the vitreous. We hypothesized that high levels of IL-10 in such cases were due to massive infiltration of the vitreous by inflammatory cells, especially activated B lymphocytes.

An increase of IL-10 in ocular fluids during acute viral retinal necrosis and ocular toxoplasmosis has been described by Ongkosuwito et al.\textsuperscript{27} In this study, uveitis of a noninfectious origin was not associated with high IL-10 levels. In another study reported by Lacomba et al.,\textsuperscript{28} uveitis was not associated with elevated IL-10 levels in the AH. In our study, most of the patients affected with uveitis had IL-10 levels in ocular fluids below the cutoff threshold whether idiopathic or of infectious etiology.

If we consider only the IL-10 level in AH for all the patients, 11 patients (6 PIOL and 5 uveitis) among all the patients screened would be classified incorrectly. ACP accurately classified (PIOL versus non-PIOL) for 91.6% of the patients. IL-10 measurements in AH and/or vitreous may be a useful complement to ophthalmologic clinical examination of suspected PIOL.

After establishing the results of IL-10 measurements in the AH (threshold = 50 pg/mL) and the vitreous (threshold = 400 pg/mL), we recommend performing an ACP to screen patients with clinical suspicion of PIOL. Clinical suspicion of PIOL is based on (1) the knowledge that patients with PIOL are mostly women after the age of 60 years; (2) the fact that chronic posterior bilateral uveitis is unresponsive to corticosteroids; (3) the association that exists between PIOL and cellular vitritis, subretinal and retinal infiltrates, and retinal pigment epithelium alterations; and (4) typical angiographic findings (e.g., hypofluorescent, round lesions and RPE disturbances).\textsuperscript{30} If IL-10 levels in the AH are more than 50 pg/mL, we propose performing a diagnostic vitrectomy after neurologic work-up if the patient is free of cerebral lesions. IL-10 measurements are associated with cytologic examination of the vitreous body according to the methods fully described by Chan and Wallace.\textsuperscript{30} Cytologic examination of the vitreous remains mandatory for the definitive diagnosis of PIOL. However, an elevated IL-10 level in undiluted vitreous strengthens a suspicion of PIOL. If cytology fails to demonstrate malignant cells despite all molecular techniques and IL-10 levels in the vitreous over 400 pg/mL, a second vitrectomy possibly combined with a retinal biopsy is justified. Several studies have shown that diagnosis of PIOL in some patients required repeated vitrectomies or retinal biopsy specimens.\textsuperscript{3,5,7,8,30}

**CONCLUSION**

PIOL is a disease with a poor prognosis that frequently masquerades as posterior uveitis. Diagnosis of PIOL is often made months or years after the initial onset of ocular symptoms. Recently, Hormigo et al.\textsuperscript{14} suggested that early diagnosis and treatment result in longer survival of patients with PIOL. IL-10 measurements in the AH after an ACP is a good screening test and may reduce diagnostic delays.
