Differential Effects of ADAMTS-1, -4, and -5 in the Trabecular Meshwork

Kate E. Keller, John M. Bradley, and Ted S. Acott

PURPOSE. Matrix metalloproteinases (MMPs) degrade extracellular matrix (ECM) and increase outflow facility in anterior segment perfusion culture. One group is the ADAMTSs (a disintegrin and metalloproteinase with thrombospondin type 1 motifs). In this study, the authors examined the effects of ADAMTS-1, -4, and -5 on outflow facility and investigated their mRNA levels and protein expression in the trabecular meshwork (TM).

METHODS. ADAMTS mRNA was quantitated by qRT-PCR in TM cells exposed to TNFα, IL-1α, TGFβ2, or mechanical stretch. ADAMTS-4 mRNA was assessed in normal and glaucomatous human anterior segments perfused at physiological or elevated pressure. Immunofluorescence was used to localize ADAMTSs in human TM cells and tissue. Anterior segments in perfusion culture were treated with recombinant ADAMTSs to determine effects on outflow facility.

RESULTS. Cytokine treatment increased mRNA of all three ADAMTSs. Mechanical stretch increased ADAMTS-4 mRNA but conversely decreased ADAMTS-1 and -5 mRNA. ADAMTS-4 mRNA levels increased in response to pressure elevation in normal eyes and to higher levels in glaucomatous eyes. ADAMTS-4 protein was highly increased in the juxtacanalicular region of the TM in anterior segments perfused at increased pressure. In human TM cells, ADAMTS-4 colocalized with cortactin in podosome- or invadopodia-like structures, but ADAMTS-1 and -5 did not. Recombinant ADAMTS-4 increased outflow facility in human and porcine anterior segments, whereas recombinant ADAMTSs-1 and -5 did not.

CONCLUSIONS. These results show differential responses and expression of ADAMTS-1, -4, and -5 in human TM cells. Combined, these results suggest that ADAMTS-4 is a potential modifier of outflow facility. (Invest Ophthalmol Vis Sci. 2009;50:5769–5777) DOI:10.1167/iovs.09-3673

Elevated intraocular pressure (IOP) is a primary risk factor for the development of primary open-angle glaucoma (POAG). Normal homeostatic adjustments to IOP involve remodeling extracellular matrix (ECM) in the trabecular meshwork (TM), particularly in the juxtacanalicular (JCT) region that abuts Schlemm’s canal. In response to elevated IOP, certain proteinases are released by TM cells and are activated. In turn, these activated proteinases degrade selected ECM molecules, causing decreased resistance to aqueous humor outflow. Matrix metalloproteinases (MMPs) have been implicated in outflow resistance. Treatment of anterior segments in perfusion culture with MMPs was found to increase outflow, whereas inhibiting endogenous MMP activity by TIMP2 or synthetic MMP inhibitors reduced outflow facility. In addition, when pressures were experimentally increased in perfusion culture, there was a concomitant increase in outflow facility that coincided with increased MMP activity and ECM turnover. These two lines of evidence argue strongly that MMP regulation and controlled ECM turnover are major components in adjusting outflow resistance.

MMPs are a group of 23 related proteinases that are synthesized as inactive proenzymes calledzymogens. Proteolytic removal of the prodomain releases the active enzyme, which then cleaves a wide variety of substrates including collagens, proteoglycans, cell-surface receptors, growth factors, and cytokines. In TM cells, certain MMPs localize to specialized cellular structures termed podosome- or invadopodia-like structures (PILS). Targeting or compartmentalization of MMPs to such structures may increase their local concentration and focus their catalytic activity to selected substrates in the pericellular environment.

Like MMPs, ADAMTSs function in many biochemical and biological processes, including specific proteoglycan degradation, receptor ectodomain shedding, activation of cell surface receptors and growth factors, fibrillar collagen processing, and cell migration. ADAMTSs are synthesized as proenzymes and have a domain structure consisting of an N-terminal prorelin domain and a C-terminal ancillary region. Perhaps the best characterized of the ADAMTSs are the aggrecanases, including ADAMTS-1, -4, and -5, which were initially shown to degrade the large chondroitin sulfate-substituted proteoglycan, aggrecan in cartilage. Various studies suggest that certain ADAMTSs are expressed in the TM and may be active. DNA microarray analysis of porcine TM cells in culture showed that tumor necrosis factor α (TNFα) and interleukin-1α (IL-1α) stimulated mRNA expression of ADAMTS-4, -5, -7, and -13. These cytokines are upregulated in response to laser trabeculoplasty, a common treatment to relieve IOP elevation in patients with glaucoma. Stimulation of glaucomatous TM cells with transforming growth factor β2 (TGFβ2), whose concentration increases in aqueous humor from patients with glaucoma, increased ADAMTS-5 mRNA expression. A neoeptope of versican, which is exposed after ADAMTS-1 or -4 cleavage, was found to localize to PILS and to areas of the TM that experience high segmental outflow.

To further examine the role of ADAMTSs in the TM, we investigated ADAMTS-1, -4, and -5 mRNA expression and protein immunolocalization in cells and tissue and evaluated the effects of recombinant ADAMTSs on outflow facility in porcine and human anterior segments.

**Materials and Methods**

**Cell Culture**

Human TM cells were dissected from donor eyes and were cultured in Dulbecco’s modified Eagle’s medium (DMEM; Sigma-Aldrich, St. Louis, MO) containing 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin-human insulin (Fungizone, as described previously.24 These studies were conducted in accordance to the tenets of the Declaration of Helsinki. Cells were used between passages 3 and 5. For mechanical stretch experiments, cells were plated in cell culture inserts and placed in six-well plates. After changing to serum-free medium, cells plated on the insert membranes were mechanically stretched over a glass bead for 12, 24, or 48 hours, as described previously.25

**Quantitative RT-PCR**

Total RNA from TM tissue, TM cells was dissected from the anterior segment after perfusion and homogenized in 0.5 mL reagent (TRizol; Invitrogen). Total RNA was isolated according to the manufacturer’s instructions, and the pellet was resuspended in 20 μL diethyl pyrocarbonate (DEPC)-treated water. Because the typical yield of RNA was low (<3 μg/μL), amplification of RNA was performed (MessageAmp II RNA amplification kit; Ambion, Austin, TX). RNase was destroyed by heating to 75°C for 10 minutes, and genomic DNA was degraded by adding DNase I for 15 minutes at 37°C, which was then inactivated by heating to 75°C for 15 minutes. Samples were stored at −20°C.

Samples were stored at −20°C.

**Western Blot Analysis**

Human TM cells were grown to confluence in T75-cm² flasks and treated with cytokines (as described) for 72 hours in 5 mL serum-free media. Cells were extracted with 0.5 mL RIPA buffer (25 mM Tris-HCl, pH 7.2, 150 mM NaCl, 1% NP-40, 1% sodium deoxycholate, and 0.1% SDS) containing protease inhibitor cocktail and 1 mM EDTA for 5 minutes on ice. Cells and ECM were scraped from the flask, and cell debris was pelleted by centrifugation at 12,000g for 15 minutes at 4°C. Proteins in 30 μL supernatant were separated on 10% SDS-polyacrylamide gels (Ready gels; Bio-Rad) and transferred to nitrocellulose membrane. Membranes were probed with an anti-C-terminal ADAMTS-4 rabbit polyclonal antibody (Millipore, Temecula, CA) and detected using a goat anti-rabbit antibody (IRDye680; Li-Cor Biosciences, Lincoln, NE). Membranes were scanned on an imaging system (Odysey Infrared; Li-Cor) with companion software (Odyssey 2.0; Li-Cor).

**Anterior Segment Perfusion Culture**

For perfusion culture, human and porcine eyes were prepared as described previously.27,28,29 Human donor eye pairs were acquired from Oregon Lions Eye Bank (Portland, OR). A summary of characteristics of normal and glaucoma donor eyes used for assessing ADAMTS-4 mRNA expression are shown in Table 1. For human eyes, the time from death to culture was not more than 48 hours, and the anterior segments were placed in stationary organ culture in serum-free DMEM for 5 to 7 days to allow the recovery of cells postmortem. Porcine eyes were acquired from Carlton Packing (Carlton, OR) and were dissected within 3 hours of death. Anterior segments were then clamped into a perfusion apparatus, and serum-free DMEM was perfused at a constant pressure of 8.8 mm Hg, giving a flow rate of 1 to 7 μL/min for human eyes or 2 to 8 μL/min for porcine eyes. These rates are similar to normal physiological rates and pressures found in vivo. Eyes that could not be stabilized at these flow rates were discarded.

After approximately 24 hours of stable flow rates, treatments were initiated. For human eyes that were subject to elevated pressure, one eye of each pair was subject to double the pressure (~16 mm Hg), which increased the flow rate to approximately 12 to 15 μL for another 24 hours (for RNA isolation experiments) or 48 hours (for protein immunolocalization experiments). For ADAMTS treatments, recombinant ADAMTSs (Millipore) were applied by direct in-line injection of the enzyme into the intake flow tube. One microgram or 0.5 μg recombinant ADAMTS-4 (Millipore; specific activity 3.7 nmol hydrolyzed substrate/min/mg ADAMTS-4) was placed in 100 μL buffer containing 50 mM Tris, pH 7.5, 150 mM NaCl, and 1 mM CaCl₂. Control eyes were injected with buffer alone. One microgram recombinant ADAMTS-5 (specific activity, 5 nmol hydroxylated substrate/min/mg ADAMTS-5) and 2 μg ADAMTS-1 (specific activity, 1.4 nmol hydroxylated substrate/min/mg ADAMTS-1) were also tested. Serum-free media were perfused for another 24 to 48 hours.

Outflow rates were plotted as time (hours) versus normalized flow rate. For each eye, the flow rates before the start of treatment (~30 to 0 hours) were averaged to provide a baseline flow rate. Actual flow rates of each eye were then divided by this baseline flow rate to generate a “normalized” flow rate.27,28,29 Data from individual experiments were then combined and averaged, and the SEM was calculated. Time point 0 represents the start of treatment. The number of eyes used for each treatment is noted in each figure legend. A paired Student’s t-test or a Mann-Whitney ranked sum test was performed to determine significance. P < 0.05 was considered significant.

**Immunostaining and Confocal Microscopy**

Human TM cells were plated into collagen type I-coated membranes (Biolox; Flexcell, Hillsborough, NC) in six-well plates and were grown for 48 hours.12 Membranes were removed from the plate with a scalpel and fixed in 4% paraformaldehyde in PBS for 5 minutes. Immunostaining of deparaffinized tissue sections and cells plated on membranes was performed, as described previously.2,12,27 All slides were blocked with 2% normal goat serum in PBS before the addition of primary antibodies diluted in PBS. Primary antibodies used were as follows: rabbit polyclonal anti-ADAMTS-4 C-terminus (Millipore or Abcam, Cambridge, UK), rabbit polyclonal anti-ADAMTS-5 C-terminus (Millipore), rabbit polyclonal anti-ADAMTS-1 C-terminus (Abcam), monoclonal anti-versican (Kamiya Biomedical, Seattle, WA). Negative controls

substituting PBS for the primary antibody were also performed. Secondary antibodies were Alexa Fluor 488 nm-conjugated goat antimouse and Alexa Fluor 594 nm-conjugated goat anti-rabbit (Molecular Probes, Eugene, OR). Coverslips were mounted with gold mounting medium (Prolong; Molecular Probes), which contains the DNA-binding dye 4',6-diamidino-2-phenylindole (DAPI).

Anterior segments were removed from the flow chambers, and the tissue was immediately fixed in 10% neutral-buffered formalin for at least 24 hours, as described previously.12,27 Eyes were cut into approximately 8 to 10 wedges, each of which was embedded into a single paraffin block, and 5-µm serial radial sections were cut approximately perpendicular to Schlemm’s canal at the pathology/histology core facility of the Knight Cancer Institute (Oregon Health & Science University, Portland, OR). Thus, each paraffin section contained tissue from 8 to 10 regions around the eye. At least three eyes per treatment were analyzed. After deparaffinization and hydration, immunostaining was performed as above. At least five sections for each antibody were evaluated by immunofluorescence.

Tissue sections and randomly selected fields from collagen type I-coated membranes (Bioflex; Flexcell) were visualized and imaged by confocal microscopy (Fluoview 1000; Olympus, San Diego, CA). Each channel was scanned sequentially to maximize separation of colors. Confocal images were processed using either Olympus software (Fluoview FV1000) or ImageJ software (developed by Wayne Rasband, National Institutes of Health, Bethesda, MD; available at http://rsb.info.nih.gov/ij/index.html).

RESULTS

mRNA Levels in Cytokine-Treated TM Cells

Various treatments were used to assess ADAMTS-1, -4, and -5 mRNA levels in TM cells (Fig. 1A). The cytokines TNFα and IL-1α are induced by laser trabeculoplasty, and both increase outflow facility in human anterior segments.7,21,22 Concentrations of TGFβ2 are increased in the aqueous humor of patients with glaucoma, and TGFβ2 decreases outflow facility in perfusion culture.29–31 Thus, TNFα/IL-1α and TGFβ2 seem to induce opposite effects in TM cells. ADAMTS mRNA expression was also investigated in response to mechanical stretch because TM cells likely sense increased IOP as a mechanical stretch via integrins or other cell-surface receptors.2,6,9,25,32

ADAMTS-1 mRNA was increased approximately 2.5-fold in response to TNFα, IL-1α, or their combination and by 1.5-fold for TGFβ2 at 12 hours, but not at other time points. Mechanical stretch did not significantly affect ADAMTS-1 mRNA. TNFα increased ADAMTS-4 mRNA levels approximately 1.5-, 3-, and 1.9-fold at 12, 24, and 48 hours, respectively. IL-1α also increased ADAMTS-4 mRNA approximately 2-fold at 12 and 24 hours, whereas the combination of TNFα and IL-1α seemed to have a synergistic effect at 12 hours, inducing a 4-fold increase in mRNA levels. TGFβ2 did not significantly affect ADAMTS-4 mRNA. Mechanical stretch increased ADAMTS-4 mRNA over time, from 1.9-fold at 12 hours to 3-fold at 48 hours. ADAMTS-5 mRNA levels in cytokine-treated TM cells.
mRNA was increased by TNFα and a combination of TNFα and IL-1α by 2.5-fold at 24 hours only. Neither TGFβ2 nor mechanical stretch significantly affected ADAMTS-5 mRNA levels. In untreated TM cells and tissues, relative mRNA levels of ADAMTS were ADAMTS-4>ADAMTS-5>ADAMTS-1 (data not shown).

To investigate whether ADAMTS-4 protein levels were also increased after cytokine treatment of human TM cells, Western blot analysis of RIPA cell lysates was performed (Fig. 1b). Multiple species of ADAMTS-4 were found, consistent with previous reports of proteolytic processing of the ADAMTS-4 C-terminal ancillary region.33–35 Full-length ADAMTS-4 (p100) and two other species (p75 and p60) that represented active ADAMTS-4 were detected using a C-terminal antibody (Fig. 1b). The p75 form represented ADAMTS-4 after furin proteolytic removal of the N-propeptide, and p60 is a form that has its N-propeptide and a portion of its C-terminal removed. Levels of the p100 form were difficult to detect because presumably the N-propeptide is cleaved relatively quickly during secretion. Other bands were also detected, but their identities are unknown. The cleaved N-propeptide was detected in the media using an N-terminal-specific antibody (data not shown). Protein levels for human TM cells treated with TNFα, IL-1α, and the combination of TNFα and IL-1α were consistently higher than the untreated control and TGFβ2-treated lanes.

ADAMTS-4 mRNA Expression in Perfused Anterior Segments

Given that ADAMTS-4 mRNA was found to increase when TM cells in culture were subject to mechanical stretching (Fig. 1), we also investigated whether ADAMTS-4 mRNA was altered when human anterior segments were subject to increased pressure in perfusion culture. These responses were compared between glaucoma donor eyes and control eyes with no history of glaucoma (normal; Table 1). For each eye pair, one anterior segment was perfused at physiological pressure, whereas the contralateral eye was subject to 2× elevated pressure for 24 hours. ADAMTS-4 mRNA was generally higher in control eyes from healthy subjects than in glaucoma donor eyes (Fig. 2A). In anterior segments subject to elevated pressure, ADAMTS-4 mRNA levels were similar between normal and glaucomatous anterior segments. When expressed as a ratio, increased pressure caused a 2.5-fold increase in ADAMTS-4 mRNA in normal eyes and a 3.4-fold increase in glaucoma eyes (Fig. 2B).

Immunostaining of ADAMT2s in Human TM Cells

To determine the immunolocalization of ADAMT2s in human TM cells, double immunolabeling experiments using cortactin and ADAMTS-1, -4, or -5 antibodies were performed. Cortactin is a marker of PILS.12 Double-immunolabeling experiments showed that ADAMTS-4 (red) colocalized with cortactin (green) at PILS (yellow colocalization; Figs. 3C, D). ADAMTS-4 was present in typical rhomboid-shaped PILS and in other PILS structures, including rosettes. In nearly all PILS that were present, as defined by positive cortactin immunostaining, ADAMTS-4 was colocalized. Conversely, ADAMTS-1 and ADAMTS-5 staining patterns were different and were generally much diminished compared with ADAMTS-4 immunostaining. ADAMTS-1 immunostaining was localized within the cytoplasm, especially in the perinuclear region (Figs. 3A, B). There was little or no colocalization with cortactin at PILS. ADAMTS-5 staining was also present as a diffuse pattern localized in the cytoplasm (Figs. 3E, F). There was little colocalization with cortactin in rhomboid-shaped PILS or in rosette structures. However, there did seem to be a small
amount of colocalization with cortactin in thin lines of staining at the cell surface (Fig. 3E).

**Immunostaining of ADAMTS-4 in Human TM**

To investigate the protein distribution in human TM tissue, anterior segments were perfused at physiological pressure for 48 hours, then fixed, and immunostaining was performed. A versican antibody was also used because versican is abundantly expressed in the TM and is a target for ADAMTS-4 cleavage.\(^{26,36,37}\) ADAMTS-4 (red) was found in a somewhat patchy expression pattern in the TM, with some staining present in the JCT region (Fig. 4A). Colocalization with versican (green; Fig. 4B) showed that much of the ADAMTS-4 staining was coincident with versican (yellow; Fig. 4C). At higher magnification, an image of the JCT region shows frequent colocalization of ADAMTS-4 and versican immunostaining (yellow), although there was a small amount of ADAMTS-4 alone detected (red; Fig. 4G).

Because the mRNA results suggested that ADAMTS-4 mRNA was upregulated in response to mechanical stretch (Fig. 1), ADAMTS-4 protein distribution was also investigated in the contralateral eye that was perfused at elevated pressure (2 ×) for 48 hours. A different pattern of ADAMTS-4 immunostaining was observed (Figs. 4D-F, H, I). In these eyes, a thin strip of ADAMTS-4 staining (red) was highly increased in the JCT region, which ran parallel to the entire length of Schlemm’s canal (Fig. 4D). This immunostaining was generally not coincident with versican (green; Fig. 4E), but a small amount of patchy staining in the outer beams of the TM did colocalize with versican (Fig. 4F). Higher magnification images showed that ADAMTS-4 expression in the JCT typically did not colocalize with versican (Figs. 4H, I).

**Recombinant ADAMTS Treatment of Anterior Segments in Perfusion Culture**

To test the effects of ADAMTSs on outflow facility, recombinant ADAMTSs were added to anterior segments in perfusion culture (Fig. 5). In porcine anterior segments, ADAMTS-4 (1 μg) was found to increase outflow facility approximately 2.6-fold in 48 hours, whereas 0.5 μg increased outflow 2.2-fold (Fig. 5A). These increases were significant (\(P = 0.0089\) and \(P = 0.0497\), respectively) when compared with average flow before treatment (Fig. 5A). There was no significant increase in normalized flow rate in response to ADAMTS-1 or ADAMTS-5 treatment. This experiment was repeated using human anterior segments (Fig. 5B). One microgram ADAMTS-4 increased outflow facility of human eyes (\(n = 3\)) approximately 2.1-fold over 24 hours (Fig. 5B). Comparable concentrations of ADAMTS-1 or ADAMTS-5 did not show similar increases in outflow facility. The increase in outflow facility was significant (\(P = 0.0438\)) when compared with the average flow before treatment. Together these results suggest that ADAMTS-4, but not ADAMTS-1 or -5, increased outflow facility in human and porcine anterior segments.

DISCUSSION

ADAMTS-1, -4, and -5 show a high degree of sequence homology and have overlapping functions, at least in terms of aggregcanolysis and cartilage degradation.33 Here, however, differential effects of ADAMTS-1, -4, and -5 are shown in mRNA levels and protein expression patterns in TM cells and in outflow facility responses to treatment with recombinant protein. ADAMTS-4 mRNA levels increased in response to mechanical stretch, whereas ADAMTS-1 and -5 mRNA did not change significantly (Fig. 1A). ADAMTS-4 localized to PILS structures in human TM cells, but ADAMTS-1 and -5 did not (Fig. 3). Recombinant ADAMTS-4 increased outflow facility in both human and porcine anterior segments in perfusion culture, but recombinant ADAMTS-1 and -5 had minimal effects (Fig. 5). These differential effects suggest that ADAMTS-4 may perform functions different from those of ADAMTS-1 or -5 in TM cells and may be an important regulator of outflow facility.

ADAMTS-4 has numerous proteolytic substrates, including versican, aggrecan, brevican, decorin, fibromodulin, and carboxymethylated transferrin.16,38 ADAMTS-1 also cleaves versican,36 but there are no reports that ADAMTS-5 has similar versicanase activity. In the TM, aggrecan is not present in appreciable amounts2,39; therefore, these other proteins must represent the major proteolytic targets in the TM. Versican is of particular interest. This is a large CS-substituted proteoglycan that interacts with many other ECM molecules, including hyaluronan, CD44, fibrillins-1 and -2, tenascin C, and fibronectin. Thus, versican serves as an attractive prospect as a major component of the outflow resistance.2 Versican is composed of two central GAG-binding domains, termed ϵGAG and βGAG, that can be included or excluded from the protein isoform by alternative mRNA splicing.40 This gives four splice forms termed V0, V1, V2, and V3. The V1 isoform is the major splice variant expressed by TM cells,26,37 and it contains the ϵGAG domain, which includes the ADAMTS-1/4 protease-sensitive site.36 Decorin and fibromodulin are both present in TM, and their mRNA levels are affected by various treatments of TM cells in culture; for example, fibromodulin mRNA is increased by mechanical stretch.2,25 These proteoglycans are members of the small, leucine-rich proteoglycans (SLRPs) and function to...
limit the lateral growth of collagen fibrils. Brevicean, like versican, is also a CS-substituted proteoglycan, but its expression is mostly limited to the central nervous system. Therefore, of the ADAMTS-4 substrates present in the TM, versican, decorin, and fibromodulin are the most likely candidates for contributing to the outflow resistance. In addition, of all the aggregcanases, ADAMTS-4 shows the highest activity on substrates other than aggregcan. This may help explain why ADAMTS-4 increased outflow facility while ADAMTS-1 and -5 had little effect.

Similar to certain MMPs, ADAMTS-4 is an enzyme that degrades ECM, increases outflow facility, and localizes to Pils. However, unlike MMPs, which tend to be localized throughout the TM, ADAMTS-4 expression increases specifically in the JCT region of the TM in response to elevated pressure (Fig. 4). Moreover, MMPs have a larger number of known substrates than ADAMTSs. This makes ADAMTSs a more attractive target for the development of new therapies for patients with POAG. However, the mechanisms by which ADAMTS-4 increases outflow facility remain unknown. Certainly, one can envision that if versican, decorin, or fibromodulin are proteolytically cleaved by ADAMTS-4, the structural integrity of the matrix is compromised, thereby allowing greater outflow of aqueous humor. Because versican interacts with many other ECM molecules, its cleavage likely leads to a major disruption of ECM interactions. Secondary effects may then occur, such as penetration of MMPs into regions that are usually inaccessible to MMP cleavage. In this regard, SLRPs, the family of proteoglycans to which decorin and fibromodulin belong, protect collagen fibrils from degradation by MMP-1 and MMP-13. Therefore, ADAMTS-4 cleavage of decorin, fibromodulin, or both may indirectly induce MMP cleavage of collagen fibrils, especially since activities of MMPs -1 and -13 are increased by similar manipulations as ADAMTS-4 (e.g., TNFα, IL-1α, and mechanical stretch).

The immunostaining pattern of ADAMTS-4 in human eyes was particularly intriguing. In eyes that were perfused at physiological pressure, there was patchy expression of ADAMTS-4 throughout the TM beams that was coincident with versican staining (Fig. 4). This colocalization may represent the congruence of ADAMTS-4 and versican at PILS located in the outer TM beams but before the cleavage of versican. Therefore, this pattern of expression may represent a portion of ADAMTS-4 that functions in normal ECM turnover; it was also observed in the outer beams of eyes subject to elevated pressure (Fig. 4). However, there was an additional pattern of immunostaining in eyes subject to elevated pressure; ADAMTS-4 was highly expressed in the JCT, in a thin strip running parallel to Schlemm’s canal. This ADAMTS-4 expression was exactly where one would expect a protease to be expressed if it were to function as a modifier of outflow resistance. This immunostaining was generally not coincident with versican staining, even though versican was present in the JCT region. The most likely explanation would be that ADAMTS-4 has cleaved versican and, therefore, that these molecules no longer colocalize. In addition, it suggests that in response to elevated pressure, ADAMTS-4 expressed in the JCT region contributes to ECM turnover and outflow resistance modification so that physiological IOP can be restored.

The activation of ADAMTS-4 is complex, and a model of ADAMTS-4 secretion and activation is proposed based on the literature and the observations presented here (Fig. 6). The N-propeptide is removed by furin-cleavage in the secretory pathway, and ADAMTS-4 is then secreted into the ECM, where the spacer domain interacts with the C-terminal domain of fibronectin. This interaction renders ADAMTS-4 inactive and sequesters it in the ECM. Fibronectin also binds the C-terminal domain of versican, and both are localized at PILS. Therefore, fibronectin may be involved in targeting both the enzyme (ADAMTS-4) and the substrate (versican) to the specific cellular location (PILS) where enzyme activation can occur. Activation of ADAMTS-4 involves proteolytic removal of the N-propeptide by furin, secreted into the ECM. In the ECM, the ADAMTS-4 spacer domain binds to the C-terminal region of fibronectin, which also binds versican. Fibronectin may be involved in targeting both the enzyme and the substrate to PILS because all three proteins localize at these cellular structures (C). Proteolytic removal of ADAMTS-4 spacer domain activates the enzyme, and it then cleaves its substrates (e.g., versican, decorin, and fibromodulin) (D).

**FIGURE 6.** Schematic of a proposed model of secretion and activation of ADAMTS-4 in TM cells. (A) ADAMTS-4 is synthesized and, after proteolytic removal of the N-propeptide by furin, secreted into the ECM. (B) In the ECM, the ADAMTS-4 spacer domain binds to the C-terminal region of fibronectin, which also binds versican. Fibronectin may be involved in targeting both the enzyme and the substrate to PILS because all three proteins localize at these cellular structures (C). Proteolytic removal of ADAMTS-4 spacer domain activates the enzyme, and it then cleaves its substrates (e.g., versican, decorin, and fibromodulin) (D).
There is some debate about whether ADAMTSs are differently regulated in normal and diseased tissues. In some studies, ADAMTS-4 levels were higher than those of ADAMTS-5 in osteoarthritic (OA) cartilage, but other reports suggest the opposite. In knockout mouse models of OA, deletion of ADAMTS-5 protected joints from cartilage destruction when OA was surgically induced, whereas ablation of ADAMTS-4 did not. Again, this suggests differential effects of ADAMTSs in tissue. Here, we show that normal TM tissue has a higher level of ADAMTS-4 mRNA than glaucoma TM tissue (Fig. 2). When the TM is subject to increased pressure, TM cells respond by increasing ADAMTS-4 mRNA levels in both diseased and nondiseased tissues. This was consistent with the increase in mRNA induced by mechanical stretch of TM cells in culture (Fig 1A). However, glaucomatous TM cells produced a much greater response (3.4-fold) than normal TM cells (2-fold), suggesting that glaucoma TM cells synthesize more ADAMTS-4 than normal tissues when attempting to correct outflow resistance. Differences between normal and glaucoma TM cells may also explain TM cell responses to TGFβ2 treatment. TGFβ2 increased ADAMTS-5 mRNA levels in glaucomatous TM cells, but there was little effect of TGFβ2 on ADAMTS-5 mRNA in normal TM cells (Fig 1A). Therefore, in response to elevated IOP or increased TGFβ2 concentrations in the aqueous humor, glaucoma TM cells may overstimulate the synthesis of ADAMTS-4 or -5, or both.

In summary, ADAMTS-4 is another Zn^{2+}-dependent metalloproteinase that increases outflow facility in vitro. It is expressed strongly in the JCT region of the TM when anterior segments are subject to increased pressure. More studies are required to identify the substrate(s) of ADAMTS-4 in the TM, as part of our overall goal, of identifying ECM components that are the source of the outflow resistance in the TM.
