Antibody-Mediated Retinal Pericyte Injury: Implications for Diabetic Retinopathy

Yan Li, Dawn Smith, Qing Li, Nader Sheibani, Suber Huang, Timothy Kern, Ram H. Nagaraj, and Feng Lin

PURPOSE. To test the hypothesis that autoantibodies against retinal pericytes could develop in diabetic retinopathy, and that these autoantibodies could induce retinal pericyte dysfunction/death via complement.

METHODS. Human primary retinal pericytes cultured in media containing normal (5 mM) or high (30 mM) glucose concentrations were incubated with normal human sera in the presence of a retinal pericyte-reactive antibody, then their viability was assessed by a BCECF-based cytotoxicity assay, and their function was assessed by a T-cell proliferation assay. The pericytes were also analyzed by RT-PCR and flow cytometry to detect CD38, an established diabetes-associated cell surface autoantigen. The potential of the anti-CD38 antibodies in inducing pericyte cellular injury was evaluated using the same cytotoxicity assays. In addition, autoantibody-mediated cytotoxicity in mouse retinal pericytes sensitized by sera from mice with developing diabetic retinopathy or control normal mice were also studied.

RESULTS. Retinal pericyte-reactive antibodies induced cellular damage by activating complement in the serum. The antibody-injured pericytes had reduced efficacy in inhibiting T cells. Hyperglycemic culture conditions rendered pericytes more susceptible to antibody-mediated attack. CD38 was expressed in retinal pericytes, and upregulated by TNF-α and IFN-γ, and anti-CD38 antibodies induced pericyte cytotoxicity. Retinal pericytes sensitized with sera from chronic diabetic mice suffered significantly augmented cytotoxicity compared with those sensitized with sera from the control mice.

CONCLUSIONS. The autoantibody-initiated complement activation could be a mechanism underlining the loss of function, and eventually, death of retinal pericytes in diabetic patients, suggesting that inhibiting complement activation could be a novel therapeutic approach. Human and Mouse Retinal Pericytes

Most of the studies in this report used human retinal pericytes that were isolated from two sets of eyes of two nondiabetic donors (aged 41 and 72, Cleveland Eye Bank) and characterized as described previously. Primary retinal pericytes were maintained in complete Dulbecco’s modified Eagle’s medium (DMEM) with 10% fetal bovine serum (FBS; Invitrogen, Grand Island, NY). For culture under hyperglycemic conditions, pericytes were cultured in complete high-glucose DMEM (30 mM glucose; Invitrogen) with 10% FBS for 7 days with daily media change. Retinal pericytes with passage numbers 3 to 5 were used in all the experiments. The ex vivo experiments used mouse retinal pericytes that were isolated from immortalized expressing a temperature-sensitive simian virus (SV), 40 large T antigen (Charles River Laboratory, Wilmington, MA), and characterized as described before. Investigative Ophthalmology & Visual Science, August 2012, Vol. 53, No. 9
Retinal Pericytes Cell Surface CD38 Expression Detection

The presence of CD38 transcripts in the retinal pericytes was examined by RT-PCR after total RNA isolation with Trizol (Invitrogen), and reverse transcribed with random primers using a first-strand cDNA synthesis kit (Invitrogen). The primers used to amplify a 397-bp CD38 transcript were located on different exons to avoid false-positive results (P1, GTTTCGAGAAGCTGCTGCTGTGATGT, and P2, ACCAGCAGGTATGCTGCTGTGATGT). The PCR reactions were carried out on a PTC-200 thermal cycler (MJ Research, Waltham, MA) with the following conditions: 94°C, 30 seconds, 58°C, 60 seconds, and 72°C, 60 seconds, 40 cycles. To detect CD38 protein on the cell surface of retinal pericytes, 2 × 10⁵ cells were cultured with or without 20 ng/mL of TNF-α (PeproTech, Rocky Hill, NJ), 300 U/mL of IFN-γ (PeproTech) or both for 48 hours. After this, the cells were stained with 10 μg/mL of an anti-CD38 IgG (Clone HIT2; Biolegend, San Diego, CA), or the same concentration of isotype control, following by flow cytometry analysis on a flow cytometer (LSR II; BD Bioscience, San Jose, CA).

Antibody-Mediated Cytotoxicity Assay

An amount of 2 × 10⁶ retinal pericytes were preloaded with 5 μM of 2′,7′-bis(2-carboxyethyl)5-carboxyfluorescein acetoxyethyl ester (BCECF-AM; Invitrogen) for 30 minutes at 37°C, then incubated with 2 μg/mL of anti-HLA ABC IgG (Clone W6/32; Biolegend) or 20 μg/mL anti-human CD38 IgG (Clone HIT2; Biolegend) in 100 μL of PBS buffer with 5% BSA for 30 minutes on ice. After washing, these antibody-sensitized pericytes were tested in a standard BCECF release-based cytotoxicity assay. In brief, sensitized pericytes were incubated with different amounts of normal human sera (NHS) or respective complement-depleted sera (Complementtech, Rocky Hill, NJ), 300 U/mL of IFN-γ (PeproTech) or both for 48 hours. After this, the cells were stained with 10 μg/mL of an anti-CD38 IgG (Clone HIT2; Biolegend, San Diego, CA), or the same concentration of isotype control, following by flow cytometry analysis on a flow cytometer (LSR II; BD Bioscience, San Jose, CA).

Retinal Pericyte Function Assay

Function of retinal pericytes was assessed based on a T-cell proliferation assay following protocols described before. In brief, freshly prepared human peripheral blood mononuclear cells (PBMCs) (Stem Cell Facility at Case Western Reserve University, Cleveland, OH) were first labeled by incubating them with 0.3 μM of carboxyfluorescein succinimidyl ester (CFSE) (Invitrogen) at 37°C for 8 minutes. After washing, T cells were activated by incubation with anti-CD3/CD28 Dynabeads (Invitrogen) following manufacturer-provided protocols. The CFSE-labeled, and anti-CD3/CD28-activated cells were then aliquoted into wells of a 96-well plate at a concentration of 0.4 × 10⁶ cells/well, and incubated with different numbers of RPMCs (RPC: T-cell ratio: 0, 1:10, 1:20, and 1:40) in triplicates. After 3 days of incubation, T-cell proliferation was assessed by measuring CFSE dilution using flow cytometry, gating on CD4⁺ T cells. The inhibition of T-cell proliferation was also calculated using the following equation: % of inhibition = (1 - [A - B]/[C - B]) × 100%, where A represents the mean experimental BCECF release, B represents the mean spontaneous BCECF release, and C represents the mean maximum BCECF released that was induced by incubating cells with 0.1% SDS.

Ex Vivo Mouse Pericyte Assay

C57BL/6 mice were injected with streptozotocin to induce diabetes, and were maintained diabetic for 10 months following protocols described before. Sera samples were collected from 10 of these chronic diabetic mice and six age-matched control mice. Mouse retinal pericytes were labeled with BCECF and incubated with 30% of sera pooled from the diabetic mice or control mice. After the antibody sensitization, these cells were then incubated with different amounts of NHS and analyzed in the same BCECF-based cytotoxicity assay.

Statistical Analysis

All experiments were repeated at least twice with similar results. The data were analyzed using an independent t test. Probability values less than 0.05 were considered to be significant.

RESULTS

Retinal Pericytes Are Injured by Complement in the Presence of a Reactive Antibody

We first examined whether retinal pericytes could be injured by complement in the presence of a pericyte-reactive antibody using a conventional BCECF leakage-based cytotoxicity assay. Because no anti-human retinal pericyte antibody has been identified, we used an anti-HLA ABC antibody as a model antibody to sensitize the primary retinal pericytes for this proof-of-concept experiment. After incubating the antibody-sensitized retinal pericytes with 5, 10, or 20 μL of NHS, we assessed cytotoxicity by measuring levels of BCECF that leaked into the culture supernatants. These assays showed that NHS induced BCECF leakage from retinal pericytes in a dose-dependent manner, consistent with a possibility that the antibody-sensitized retinal pericytes were injured by complement (Fig. 1A). To further confirm the role of complement in the antibody-induced pericyte cytotoxicity, we again incubated antibody-sensitized retinal pericytes with 30 μL of NHS, or complement-depleted human sera (C3-dep or C5-dep), then assessed pericyte cytotoxicity using the same assay. These experiments showed that although NHS induced retinal pericyte cytotoxicity (as reported above), the same amount of C3- or C5- depleted sera had minimal effect on inducing BCECF leakage (Fig. 1B). This indicates that complement plays a primary role in inducing pericyte cytotoxicity in the presence of pericyte-reactive antibodies, and that the terminal pathway of complement activation (starts from C5) is required for NHS to injure pericytes.

Hyperglycemic Conditions Render Retinal Pericytes More Susceptible to Antibody-Mediated Attack

We next asked whether hyperglycemic conditions found in diabetic patients make retinal pericytes more susceptible to the autoantibody-mediated attack. We first cultured retinal pericytes in normal-glucose media (5 mM) or high-glucose media (30 mM) for seven days with daily media change, and then compared the severity of antibody-mediated injury by measuring BCECF leakage in the presence of different amounts of serum. These assays showed that retinal pericytes cultured in the high-glucose media had a greater leak of BCECF than cells cultured in the normal glucose media (Fig. 2), indicating that even seven days of high-glucose conditions is enough to make pericytes more susceptible to antibody-mediated attack.
Antibody-Injured Retinal Pericytes Have Impaired Immunosuppressive Function

We recently demonstrated that retinal pericytes inhibit the proliferation of activated T cells, and protected retinal endothelial cells from inflammation-induced apoptosis. To test whether pericyte-reactive antibodies have any effect on the function of retinal pericytes in the presence of serum, we compared the ability of antibody-sensitized retinal pericytes incubated with or without NHS to inhibit activated T cells using the same CSFE-based T-cell proliferation assay as we have done before. These experiments showed that antibody-sensitized retinal pericytes incubated with NHS had significantly reduced T-cell inhibitory activity compared with those without NHS incubation, indicating that the antibody-injured retinal pericytes had impaired cellular function (Fig. 3).

Autoantigen CD38 Is Expressed in Retinal Pericytes

In the above studies we used an anti-HLA mAb as a model antibody to sensitize the retinal pericytes. Trying to identify clinically associated autoantibodies that could bind to the cell surface of retinal pericytes to activate complement, we examined whether CD38, an established diabetes-associated cell surface autoantigen, is expressed in retinal pericytes by RT-PCR and by flow cytometry. We found that CD38 transcripts were detectable by RT-PCR in the quiescent retinal pericytes (Fig. 4A); however, pericyte cell surface levels of CD38 protein were low (as examined by flow cytometry; not shown) under normal culture conditions. Because local inflammation develops early in diabetes, and inflammatory cytokines TNF-α and IFN-γ have been associated with diabetic retinopathy, we then treated the retinal pericytes with TNF-α and/or IFN-γ, and assessed the levels of CD38 protein on retinal pericyte cell surface by flow cytometry again. These studies showed that after 48 hours of treatment, TNF-α alone, but not IFN-γ alone, upregulated CD38 expression on retinal pericytes, and that TNF-α and IFN-γ together had a synergistic effect on upregulating CD38 on the surface of retinal pericytes (Figs. 4B, 4C).

Anti-CD38 IgGs Induce Retinal Pericyte Cytotoxicity

We next examined whether anti-CD38 IgGs could induce retinal pericyte cytotoxicity like the anti-HLA IgGs tested above, and whether inflammatory conditions commonly found in diabetic retinopathy patients could augment the anti-CD38 antibody-induced cytotoxicity. We first cultured retinal pericytes with or without TNF-α/IFN-γ, then incubated them with the same amount of anti-CD38 IgGs. After this, we incubated the antibody-sensitized pericytes with different amounts of NHS, and assessed their cytotoxicity by measuring levels of leaked BCECF. These assays showed that similar to what was discovered in studies using the anti-HLA model antibodies, anti-CD38 IgGs induced retinal pericyte cytotoxicity, and that inflammatory cytokines TNF-α/IFN-γ significantly augmented the cellular injury (Fig. 5).

Sera from Chronic Diabetic Mice Induce Retinal Pericyte Cytotoxicity

We next tried to verify these in vitro results in vivo by examining whether sera from diabetic mice (with developing retinopathy) could induce retinal pericyte cytotoxicity. We induced diabetes in mice by streptozotocin injection, and maintained the mice diabetic for 10 months. After this, we collected and pooled sera from these diabetic mice and age-matched normal mice, then incubated mouse retinal pericytes with the respective sera to allow any pericyte-reactive antibodies to bind. After washing, we incubated the
sensitized pericytes with NHS, and assessed their viability by measuring BCECF leakage. These studies showed that pericytes sensitized with sera from the chronic diabetic mice had markedly increased levels of BCECF leakage after incubation with serum (Fig. 6), indicating that like anti-HLA IgGs and anti-CD38 IgGs tested in the above human pericyte studies, autoantibodies developed in chronically diabetic mice induced significantly increased pericyte cytotoxicity compared with those in the control mice.

**DISCUSSION**

In this report, we found that retinal pericytes were injured by complement in the presence of an antibody that reacted with pericyte cell surface antigens. Hyperglycemic conditions rendered retinal pericytes more susceptible to antibody-mediated injury, and the injured retinal pericytes had reduced activity to inhibit T cells (as a parameter of pericyte function). CD38, an established cell surface autoantigen in diabetes, was expressed in retinal pericytes and upregulated by TNF-α and
IFN-γ. Anti-CD38 IgGs also induced pericyte cytotoxicity in the presence of serum, and TNF-α/IFN-γ augmented this effect. Finally, retinal pericytes sensitized with sera from chronic diabetic mice suffered more severe cellular injury in the presence of serum than those sensitized with sera from the control mice.

Evidence suggests that loss of retinal pericytes likely contributes to the development of diabetic retinopathy, so it is important to understand the mechanisms of retinal pericyte death in diabetes. Vascular permeability is increased in diabetes, in which case components in the blood including complement and autoantibodies have access to retinal pericytes. The possibility that autoantibodies might contribute to the development of pericyte loss and other lesions of diabetic retinopathy has been inadequately studied. One group reported that antibodies from diabetic patients cross-reacted with bovine retinal pericytes,\textsuperscript{20,21} but evidence that autoantibodies against human retinal pericytes developed in diabetic patients remains absent, and the possible underlying mechanism is unclear. To test the hypothesis that retinal pericyte-reactive antibodies can induce pericyte cytotoxicity through activating complement, we first used an mAb against the HLA, which is present on retinal pericytes. We sensitized human primary retinal pericytes with the anti-HLA antibodies, then incubated the cells with NHS, or complement-depleted sera. These proof-of-concept experiments demonstrated that pericytes can be injured, and their function can be impaired by autoantibodies through activating complement.

CD38 (ADP-ribosyl cyclase/cADPR hydrolase) has been identified as an autoantigen in diabetes patients.\textsuperscript{16} CD38 is a cell surface protein that is present on many types of cells, including T and B cells, monocytes, neuronal cells, and islet

cells. The presence of anti-CD38 autoantibodies was first described in a Japanese cohort of type 2 diabetes patients. Studies from several other groups confirmed this result in different ethnic patient populations. Anti-CD38 autoantibodies were also identified in type 1 diabetes and the prevalence of anti-CD38 autoantibodies was found to be higher with longer duration of diabetes. Although anti-CD38 autoantibodies have been detected in both type 1 and type 2 diabetes, their potential pathological roles were unclear, and whether CD38 is expressed in retinal pericytes was not studied. Our results provide evidence for the first time that CD38 is present on retinal pericytes and is upregulated under inflammatory conditions. These results, together with the reports that anti-CD38 autoantibodies are identified in diabetic patients, support the concept that autoantibodies against surface antigens on retinal pericytes can develop in chronic diabetic patients.

After binding to self-tissues, autoantibodies can activate complement, which contributes to the pathogenesis of many autoimmune diseases, including myasthenia gravis and membranous glomerulonephritis. Complement activation products are detectable in retinal vasculatures in diabetic patients, however, whether the activated complement could be involved in the dysfunction and loss of retinal pericytes was completely unknown. We found that antibody-sensitized pericytes were injured by NHS but not C3- or C5-depleted serum, and that the complement-injured pericytes had reduced efficacy in inhibiting T cells, suggesting that complement could contribute to the dysfunction and loss of retinal pericytes in diabetic patients.

Based on these data, we propose that complement activation contributes to the functional loss and death of retinal pericytes in diabetes. Especially in patients with type 1 diabetes, autoantibodies develop as a result of islet destruction and other autoimmune conditions. Some of these autoantibodies (including anti-CD38 IgGs) recognize cell surface antigens on retinal pericytes. Under chronic inflammatory conditions in these patients, permeability of the retinal vasculature is increased, which allows retinal pericyte-reactive autoantibodies and complement in the blood to access retinal pericytes. Inflammatory cytokines also upregulate autoantigens, including CD38, on retinal pericytes in diabetic patients. Complement is activated by the autoantibodies binding to surface antigens on retinal pericytes, leading to cytotoxicity, reduced activity, and, eventually, retinal pericyte loss. Our data also suggest that controlling complement activation in diabetic patients could be a new approach for preserving the function and preventing the loss of retinal pericytes in diabetes, which could help to prevent the development of diabetic retinopathy.
